Kilobot: A Low Cost Scalable Robot System for Collective Behaviors

Michael Rubenstein, Nicholas Hoff, Radhika Nagpal

Abstract—In current robotics research there is a vast body of work on algorithms and control methods for groups of decentralized cooperating robots, called a swarm or collective. These algorithms are generally meant to control collectives of hundreds or even thousands of robots; however, for reasons of cost, time, or complexity, they are generally validated in simulation only, or on a group of a few 10s of robots. To address this issue, this paper presents Kilobot, a low-cost robot designed to make testing collective algorithms on hundreds or thousands of robots accessible to robotics researchers. To enable the possibility of large Kilobot collectives where the number of robots is an order of magnitude larger than the largest that exist today, each robot is made with only $14 worth of parts and takes 5 minutes to assemble. Furthermore, the robot design allows a single user to easily oversee the operation of a large Kilobot collective, such as programming, powering on, and charging all robots, which would be difficult or impossible to do with many existing robotic systems. We demonstrate the capabilities of the Kilobot as a collective robot, using a 25 robot test collective to implement three popular swarm behaviors: foraging, formation control, and synchronization.

I. INTRODUCTION

A large group of decentralized closely cooperating entities, commonly called a collective or swarm, can work together to complete a task that is beyond the capabilities of any of its individuals. Many such examples can be found in nature: army ants and honeybee colonies effectively forage over large areas many kilometers wide; desert ant groups can collectively transport large irregular objects 50 times their collective weight; termite colonies construct mounds meters tall even though individuals are only a few millimeters tall themselves. These examples from nature have inspired long-standing research in collective robotics to achieve the kind of parallelism, robustness and collective capability of these natural systems.

Within robotics, there is a wide range of active research topics that explore algorithms to control these robotic collectives, such as self-assembly [11][21][19], collective construction [5][9], and exploration [8][24], to name a few. Researchers commonly envision these algorithms to operate on collectives of hundreds [5], thousands [21][19], or more [11][15] robots; however, for reasons of cost, time, or complexity, they are generally validated in simulation only [11][19], or on a group of a few 10s of robots or fewer [6][20]. When using a simulation to validate an algorithm for a collective of robots, it is difficult to accurately model robots’ interaction with each other, such as communication and sensing, and with the environment, such as movement and collisions. This modeling difficulty can lead to disparities in algorithm behavior when operating on a simulated collective versus a real robotic collective. Additionally, operating an algorithm designed for a large collective of robots on just a few may hide scaling issues within the algorithm that can only be uncovered in a much larger collective. To better understand and validate both current and future collective control algorithms, it would be useful for these algorithms to be tested on a larger collective of real robots.

Other research groups have also recognized the importance of a collective of robots for testing and validating algorithms; however, for various reasons, most operate collectives of a few 10s of robots [12][6][3] or at the very most a few hundred robots [2][14]. These collective sizes are primarily limited by robot cost and operational complexity. The cost of an individual robot is perhaps the largest limiting factor for collective size; for a fixed budget, the lower the robot price, the larger the size of the collective. For example, a popular commercially available robot, the e-puck [3], equipped with an infrared communication ring for collective operations, costs over $1300, and as a result, is usually operated in collectives of about 10 robots. A robot more oriented towards large scale multi-robot research is the Jasmine robot [14]. This robot costs about $130 in parts and has been operated in collectives of 150 robots; however, the robot is not available for purchase.

In addition to cost, the complexity of operating the robots, such as turning the robots on/off, charging, controlling, and programming the collective, also plays a role in limiting the size of the collective. For example, a common way to control the power of a robot is to have a switch on each robot to turn the robot on and off [5][12]. If this switch takes three seconds per robot to find and flip, then it would take a single person 50 minutes to turn on a collective of 1000 robots. Furthermore, if the collective is large enough, the first robot to turn on may actually run out of power before the last robot is turned on. This manual power switch as well as other design decisions can prevent the size of the collective from scaling to large numbers.

To make a robot scalable to large collective sizes, as described in [10], all the operations of the robot must work on the collective as a whole, and not require any individual attention to the robot, such as pushing a switch or plugging in a charging cable for each robot. In other words, all collective operations must be scalable. An example of a scalable operation on a robotic collective is the programming of the I-Swarm robots [18]. In these robots, instead of plugging in a programming cable to each robot in order to update its program, each can receive a program via an infrared communication channel.
This allows an overhead infrared transmitter to program all the robots in the collective in a fixed amount of time, independent of the number of robots. Another example of scalable operations is found in [10] [13], where instead of manually plugging in each robot to a charger for battery charging, they use an automatic charging dock that allows the robots to charge themselves without human help, thus making the robot charging scalable. An example of a scalable operation regarding power control is found on the Robomote [20], and in sensor networks. Instead of powering off the robot, the robot is always on, but in a low power sleep state, ready to turn on if the appropriate command is received. As a result, a Robomote never has to be turned on or off manually, and the entire collective can be turned “on” in a fixed time independent of the number of robots. These sorts of scalable operations are essential for collective operations, but at the same time, they should not dramatically change the robots’ capabilities, cost, or ease of manufacturing.

The rest of this paper introduces a new robot, the Kilobot, which is a low cost robot with fully scalable operations. This robot is designed to make testing collective algorithms on hundreds or thousands of robots accessible to robotics researchers. First we describe the hardware design of a Kilobot robot, where its low cost ($14 worth of parts) and ease of assembly (5 min to assemble) enable large numbers to be produced easily. While these robots are low-cost, they still have abilities similar to other collective robots. These abilities include: differential drive locomotion, on-board computation power, neighbor-to-neighbor communication, and neighbor-to-neighbor distance sensing. These abilities are achieved at low cost mainly through the use of vibration based locomotion and a simple range only sensor. Next, we discuss how the operations of a Kilobot, such as programming, turning power on and off, battery charging, and starting/stoping programs, do not require any individual attention by a person, and therefore a large collective can be easily overseen by a single operator. Finally we will demonstrate that the Kilobot can be used for implementing and testing collective behaviors. These demonstrations use a 25 Kilobot test collective to implement the popular collective behaviors of foraging, formation control, and synchronization. A video showing these demonstrations is available at http://tinyurl.com/kilobot

II. KILOBOT DESIGN

Two competing factors were considered when designing the Kilobot robot: the cost, and the functionality. The Kilobot needs enough functionality to allow it to perform a wide variety of collective behaviors, while at the same time, it must be simple enough to keep the cost low. The chosen functionality for Kilobot is that it must move within its environment, run a user defined program, communicate with its neighbors, measure distance to those neighbors, display some internal state to assist with debugging, and allow for scalable operations. While these are not the minimum set of functions needed for a collective robot, they strike a balance between what behaviors a collective of robots is capable of, and the cost of that collective. This section describes the design of the Kilobot hardware which has the functionality needed, while also keeping the price low. A general overview of the Kilobot robot is given in Fig. [1]. The environment, called the “arena”, that these robots are intended to operate in, consists of a smooth, level, reflective table (e.g. a standard dry erase surface) which can be seen in Fig. [2].

A. Locomotion

One important capability of the Kilobot is that it must be able to move in its environment. The most common locomotion strategy for swarm robots is to use a two-wheeled differential drive, where each wheel is powered by an electric gear motor. While this conventional wheeled locomotion is quite effective, it is relatively expensive, as even a low-cost
The Kilobot also be able to communicate with its neighbors and sense some information about its physical relation to its neighbors. In order to keep the robot cost down, the sensing of neighbors only includes distance sensing, not bearing sensing. While bearing sensing is often used with collective robots, for example [11], distance-only sensing [19] is still sufficient for interesting collective behaviors, as section IV shows.

To communicate with neighboring robots, each Kilobot has an infrared LED transmitter and infrared photodiode receiver, which are located in the center of the PCB and are pointed directly downwards at the table the Kilobot is standing on as shown in Fig. 1. Both the transmitter and receiver have an isotropic emission or reception pattern, which allow the robot to receive messages equally from all directions. Additionally, both the receiver and transmitter are wide-angle, with an angle of half power of 60° from the robot’s downward pointing vertical axis. When the transmitter is active, any nearby robot can receive the light emitted by the transmitting robot after it is reflected off the table, as shown in Fig. 3. Messages are transmitted by pulsing the transmitter according to standard line coding technique. Using this simple communication method, a Kilobot can communicate at rates up to 30 kb/s with robots up to 10cm (about 6 robot radii) away.

With all robots using the same infrared channel for communication, there is the possibility that two or more robots may try to transmit at the same time. To mitigate this problem a standard carrier sense multiple access with collision avoidance (CSMA/CA) method is used. Even with CSMA/CA, environments with many nearby robots will experience a reduction of the channel bandwidth due to collisions. In an experiment with 25 robots, configured as shown in Fig. 2, the channel could support on average 240 five-byte packets/second, a 32% channel usage.

During any communication between robots, the receiving robot also measures the intensity of the incoming infrared light. This incoming light intensity is a monotonically decreasing function of the distance between the transmitter and the receiver; therefore the distance to the transmitter can be calculated by the receiver. In practice, the incoming intensity of light is also affected by noise and manufacturing variances, which leads to sensing accuracy of ±2 mm, and precision under 1 mm.

C. Controller

The controller for the robot serves two functions. Firstly, it interfaces with all the low-level electronics such as motors, communication, power circuitry, and the RGB LED (used for displaying information to the operator, seen in Fig. 1). Secondly, it runs a user-defined robot behavior program. The controller used is an Atmega328 microprocessor, which runs at 8 Mhz and has 32K of memory. Some key features of this controller used in the Kilobot are: two pulse width modulation (PWM) channels used for controlling the speed of the vibrating motors, 10-bit analog-to-digital converters used for measuring the incoming infrared light intensity, self-programmable memory used to update the robot’s program (described in section III-C), and a low-power sleep mode (see section III-A). The program for the robot is written in C, which allows researchers to quickly and easily develop robot behaviors.

D. Power System

To power the entire robot, each Kilobot has a 3.4 V 160 mAh lithium-ion battery, shown in Fig. [1]. This battery can power the robot for 3-10 hours depending on the robot’s activity level. Connected to this battery are three voltage regulators and a battery charger. Two of the voltage regulators provide power to the motors and the communication system. Both of these regulators can be switched on and off by the microcontroller, enabling shutdown of the motors and the communication system to conserve power consumption. The third voltage regulator continuously provides power to the microcontroller, and during low-power states (described in section [III-A]) only draws 50 µA. When the battery charger receives 6 Vdc (described in section [III-B]), the charger will begin charging the onboard battery; when the battery is charged, the charging will stop.

E. Cost

To allow for large Kilobot collectives, it is critical that each robot be as low-cost as possible. The Kilobot design as described uses about $14 worth of parts, which is at least 10 times less than the lowest cost of currently used collective robots [11]. The cost of each Kilobot can be broken down into six categories: locomotion, power, communication/sensing, control, structure (includes PCB and battery holder), and miscellaneous (all other parts, such as the RGB LED). Table I gives a summary of the cost of these six categories of Kilobot parts.

The assembly time of a robot can also affect the price of a robot if it is pre-assembled; if not, it can make building a collective difficult and time-consuming. Either way, it is important for the robot to be able to be assembled quickly. To aid in a quick assembly time, most of the robot’s components are surface-mount, and are placed using a pick-and-place manufacturing robot. The remaining parts to be assembled are: the battery holder, the legs, the motors and the infrared receiver and transmitter. The battery holder and the infrared receiver and transmitter can be assembled by hand. For the remaining parts, custom-made assembly rigs allow for quick and precise alignment and attachment of the motors and the legs. This entire assembly process takes less than five minutes.

F. Robot Capability Demonstrations

To demonstrate Kilobot capabilities, this section shows two demonstrations that provide evidence for the robot’s basic functionality: the ability to move within its environment, run a controller, communicate with its neighbors, and measure distance to those neighbors. Additionally, these demonstrations show that when Kilobots sense and communicate with neighbors, they can improve their capabilities beyond what is directly available to them in hardware. In these demonstrations, the improved capabilities shown are position sensing and bearing sensing.

1) Orbit Demonstration: In the first demonstration, a single robot is tasked to travel on a circular path. Lacking odometry, this task is not possible for a single Kilobot, as shown in Fig. [4(C)]. However, with the assistance of a stationary neighboring Kilobot acting as a marker for the center of the orbit, orbiting is possible, as shown in Fig. [4(A)]. This stationary robot sends out a message at 1/10th of a second intervals, which is received by the orbiting Kilobot. These messages allow the orbiting Kilobot to compute its current distance to the stationary robot, which is also its distance to the center of its desired orbital path. These distance measurements allow the onboard controller to compute the robot’s deviation from the ideal orbit, and using a PD controller, adjust the intensity of both motors’ vibrations to correct for it, keeping the robot close to the ideal path.

2) Path Following Demonstration: A second demonstration shows a Kilobot following a more complicated path, in this case a “U” shaped path. This path is defined in Cartesian coordinates as a polygon in which the robot is allowed to move. If the robot is inside the polygon, it moves straight, if not, it turns back towards the interior of the polygon. To enable
this behavior, three stationary robots are set in the environment in a triangle shape, as shown in Fig. 4(B). These three robots know their position in a coordinate system and communicate that position to the moving robot 10 times a second. The moving robot uses the communicated positions of the three stationary robots, as well as its measured distance to those robots, to trilaterate its own position in the coordinate system. Once the moving robot knows its position in the coordinate system, it can compute if it is located inside the polygon or not. If not, it can also compute which direction to turn in order to move back into the polygon. The position of the moving robot during five attempts at following the path is shown in Fig. 4(B).

III. A SCALABLE COLLECTIVE

With a large collective of robots, it can become tedious or even impossible to work with it if the robots require a human operator to interact with each of the robots one at a time. Some of these individual interactions could include pushing the robot’s power switch on or off, plugging in a cable to program or charge the robot, and pausing, starting, or stopping the program running on the robot. The following section explains how a Kilobot does not require any individual attention for normal collective operations; i.e., it is a scalable robot. To allow a single user to scalably operate the collective, the setup for Kilobot testing and operations has an overhead infrared controller, as shown in Fig. 2. This controller can send infrared messages, using the same methods as in II-B, to all the Kilobots on the testing arena at once. The overhead controller is in turn controlled by an operator sitting at a computer-based control station.

A. Power

To avoid a physical switch to turn the robots “on” or “off”, Kilobots use a power control scheme similar to some sensor networks and the Robomote [20]. This power control scheme works by replacing the standard “off” state of the robot, where the battery is disconnected from the robot, with a low-power sleep mode. While in this mode, the battery stays connected to the robot, but the robot powers down most of its electronics and the microprocessor goes into a sleep state for one minute. During this time, the power drawn from the battery by the Kilobot is approximately 170 $\mu$W. After one minute, the microprocessor wakes up, turns on the infrared sensor, and for 10 ms it checks if it receives a wake-up message from the overhead controller. To ensure that a message is received during this 10ms window, the overhead controller transmits the wake-up message every 3ms for over a minute. If a wake-up message is received by the robot, it switches to the standard “on” mode. If no-wake up message is received, then the robot will go back to the low power sleep mode, repeating this cycle until a wake-up message is received. If the robot is in the “on” mode, a sleep message sent from the overhead controller will switch it to the low-power sleep mode.

Using this power control scheme, the robot can remain in the low-power sleep mode, waiting to switch to the “on” mode, for more than 3 months on a single battery charge. Furthermore, the entire collective can be switched from the low power sleep mode to the “on” mode in under one minute, and from the “on” mode to the low-power sleep mode in a few seconds.

B. Charging

As described in section II-D, when 6 Vdc is applied to the input of a Kilobot’s battery charger, it will charge the on board battery until the battery is full. To apply this potential to the charger input, the top of the robot is connected to an electrical ground, and the bottom legs are connected to 6Vdc, as shown in Fig. 5(A). This enables an entire collective to be charged by first placing it onto a conductive surface, which can easily be done by pushing the whole group with a long stick as shown in Fig. 5(B). Next, a conducting board, such as a poster board coated with metallic tape, is placed on top of the collective. Finally 6Vdc is applied across the bottom conductive surface and the top conducting board, connecting the input of all the chargers to the required voltage. Fig. 5(C) shows a group of Kilobots in this charging configuration which does not require any attention to the individual robots.

C. Programming

To change the program running on the Kilobot’s microcontroller, the self-programming feature of the Atmega328 is used. This feature allows the main program code, located in the primary sector of memory, to be overwritten by a program written in a separate “bootloader” sector in memory. In this bootloader sector of memory, Kilobot has a program that receives infrared messages from the overhead controller which contain portions of the new desired main program code. It then writes these portions of code to the appropriate location in the primary sector of memory. The bootloader program has error-checking to ensure that the program placed in the primary sector is complete and error-free. Once the complete replacement program has been received, the bootloader code
resets the microprocessor, and the newly loaded main program code begins execution. When the operator desires to put a new program in all of the Kilobots, the operator transmits a “jump to bootloader” message from the overhead controller. When this message is received by the main program code, it moves the program counter to the bootloader section of code, causing the bootloader program to execute. This scalable programming scheme allows all the Kilobots present in the testing arena to load a new program in under one minute. To validate this, a test collective of 25 robots were programmed using this method in 35 seconds.

D. Other Control

In addition to programming and power control, the overhead controller is also useful in other aspects of Kilobot operations such as querying a robot’s battery voltage, and starting, restarting, and pausing the robot’s programs. For example, it may be useful for the operator to know the battery voltage of the robots in the collective to determine if they need to be recharged. To do this, the operator sends a message to all the robots via the overhead controller to display voltage. Each robot then displays a color on its RGB LED based on the measured voltage of its battery, displaying green if the battery has more than 90% charge remaining, blue if between 90% and 40% is remaining, and red if less than 40% is remaining. With all robots displaying their charge status, the operator can then look at the collective and determine its overall charge status. In addition, the operator can control the execution of the main program in all Kilobots by issuing commands via the overhead controller to pause, start, stop or restart the main program.

IV. COLLECTIVE BEHAVIOR DEMONSTRATIONS

While designed to be low cost and simple, Kilobot is still capable of interesting collective behaviors. To demonstrate this, a test collective of 25 robots was built and used to implement three popular collective behaviors. These behaviors are: ant-inspired foraging, formation control, and synchronization.

A. Foraging

Foraging is a popular biologically inspired task in collective robotics, for example [23, 13]. The task generally involves robots exploring the environment to find a “food” goal, and delivering it to the “nest”. In this demonstration, the foraging algorithm from [7] is implemented directly on a Kilobot collective. Two immobile Kilobots with specialized programs are placed as markers in the environment, as shown in Fig. 6 symbolizing the nest and food locations. These markers constantly transmit a message that tells any robots within communication range that the marker is the nest or food. For food to be delivered to the nest, a robot must pass close to the food marker, where it “picks up” a unit of food from the food marker, and then the same robot must then pass close to the nest marker, where it “drops off” the food.

In this foraging algorithm, some of the robots can take on the role of a “beacon”. The goal of this beacon is to aid the remaining robots, the “walkers”, in navigating between the nest and the food. The beacons do this by maintaining two variables, food gradient, and nest gradient. If any beacon sees the food or the nest, it sets its corresponding gradient value to one. Otherwise, the beacon sets its gradient value to be the value of the lowest corresponding gradient it receives from neighboring beacons, plus one. This allows any walker robot to listen to the nearby beacons and determine which beacon is closest to the nest or the food. If the walker does not have food, it moves towards the beacon that is closest to the food. If the walker does have food, it moves towards the beacon that is closest to the nest. A walker can move closer to a desired beacon by sensing its distance to that beacon, and then moving to reduce that distance. While moving, a walker also needs to avoid collisions with other robots. This is done by detecting if any neighbors are less than 1cm away, and if so, turning away until it no longer is. This overall movement strategy of moving towards the desired beacon while avoiding collisions allows the walkers to travel from the nest to the food and back.

Initially, as shown in Fig. 6(A), all the robots are placed next to the nest marker and have no information about the location of the food marker. They all start in the walker role and spread out from the nest. As they spread out and explore the environment, some walkers choose to become beacons.
These beacons are created to provide a connection between the exploring walkers and the nest. If, as shown in Fig. 6(B), one or more beacons see the food, then the remaining walkers will be capable of navigating to the food and nest, as shown in Fig. 6(C). For a more detailed explanation of this algorithm, please see [7].

B. Formation Control

Formation control, another biologically inspired behavior, is often applied to robotic collectives, particularly in the control of unmanned vehicles. This demonstration shows “follow-the-leader”, a popular formation control behavior often applied to robot collectives [16], and implements it on 6 Kilobots. In this demonstration, the Kilobots start lined up facing the leader. The leader then moves in its forward direction, and all the followers follow along approximately the same path. Note that as seen in Fig. 7, without positional information, the leader does not always move precisely forward; however, the other Kilobots still follow the leader.

To initialize the Kilobot collective for follow the leader, each robot is assigned an ID, where the ID of the leader robot is 1. The ID of the remaining robots is one greater than the robot immediately in front of it. This allows the robots to know the ID of the robot immediately in front and behind it. Additionally, the front robot knows that it is the leader (its ID is 1), and the last robot, the tail, knows that it has no robots behind it (it sees no ID greater than its own). All robots can operate in two states, move and wait. Initially, if the robot has an even ID, it starts in the wait state, and if its ID is odd, it starts in the move state. During the entire demonstration, each robot will constantly communicate this state and its ID to its neighbors. A robot in the wait state will stay stationary and wait until the robot immediately in front of and behind it are also in the wait state. When this condition is met, the robot will then switch to the follow state. The leader and tail robots only wait for the robot in back or in front of it respectively. During the follow state, each robot will measure the distance to the robot directly in front of it, and move to reduce this distance. Once this distance is less than one cm, the robot will stop moving and switch to the wait state. Since the leader has no robots in front of it, when it is in the follow state, it moves forward until it is four cm away from the robot directly behind it, then switches to the wait state. There are some additional nuanced rules for switching states to prevent premature state changes, but for the sake of brevity, these will not be discussed here. These two behaviors allow robots to move towards the leader robot, while at the same time not move so fast as to break communications with the robot directly behind it. The result is that the collective of Kilobots follow the leader, as shown in Fig. 7.

C. Synchronization

Synchronization is often used when coordinating simultaneous actions between many entities, such as robots or sensor networks. A popular method for synchronization [17] is based
on how fireflies synchronize their periodic light emissions in nature. In this work, each entity maintains a periodic clock that when it reaches its maximum value, the clock resets, and the entity sends a signal to its neighbors. Whenever a neighbor receives a signal, it adjusts its local clock according to when it was received. This adjustment is enough to eventually synchronize all the entities. A modification of this approach [4] is intended to operate on systems that use a communication channel where contention and delays are possible, which is true for the Kilobot system. This demonstration uses an approach closely related to [4] to synchronize the flashes of the RGB LED on 25 Kilobots. Fig. 8 shows the number of flashes for the whole collective during 0.5 second increments, demonstrating that the initially unsynchronized collective does become synchronized.

V. CONCLUSION

In this paper, we have presented the Kilobot robot, a $14 robot designed specifically for operation in a large collective. While the Kilobot is a relatively simple and low cost robot, we have shown it to be a viable collective robotic system by demonstrating three popular collective multi-robot behaviors using a 25 Kilobot test collective. The robot design and collective operations are carefully considered in order to make it easy to manufacture and operate a large collective of Kilobots. To keep the robot cost low, its design uses an unusual locomotion technique (vibration-based) and relatively simple sensing (distance but no bearing), both of which dramatically reduce the robot cost without sacrificing its functionality. As the range of collective behaviors is expanded, it may be useful to modify this choice in the robot design by adding other sensors, for example a bump sensor or an ambient light sensor. In the future, we hope to make both the Kilobot hardware designs and software openly available for others to use and to extend. Additionally, we plan on building a 1024 Kilobot collective and applying it to additional collective behaviors such as self-healing and collective transport.
